INTRODUCTION

Simulated annealing is one of the most important metaheuristics or general-purpose algorithms of combinatorial optimization, whose properties of convergence towards high quality solutions are well known, although with a high computational cost. Due to that, it has been produced a quite number of research works on the convergence speed of the algorithm, especially on the treatment of the temperature parameter, which is known as cooling schedule or strategy. In this article we make a comparative study of the performance of simulated annealing using the most important cooling strategies (Kirkpatrick, S., Gelatt, C.D. & Vecchi, M.P., 1983), (Dowsland, K.A., 2001), (Luke, B.T., 1995), (Locatelli, M., 2000). Two classical problems of combinatorial optimization are used in the practical analysis of the algorithm: the travelling salesman problem and the quadratic assignment problem.

BACKGROUND

The main aim of combinatorial optimization is the analysis and the algorithmic solving of constrained optimization problems with discrete variables. Problems that require algorithms of non-polynomial time complexity with respect to the problem size, called NP-complete problems, are the most important ones.

The general solving techniques of this type of problems belong to three different, but related, research fields. First, we can mention heuristic search algorithms, such as the deterministic algorithms of local search (Johnson, D.S., Papadimitriou, C.H. & Yannakakis, M., 1985), (Aarts, E.H.L. & Lenstra, J., 1997), the stochastic algorithm of simulated annealing (Kirkpatrick, S., Gelatt, C.D. & Vecchi, M.P., 1983), and the taboo search (Glover, F., 1986). A second kind of solving techniques are algorithms inspired in genetics and the evolution theory, such as genetic and evolutionary algorithms (Holland, J.H., 1973), (Goldberg, D.E., 1989), and memetic algorithms (Moscato, P., 1999). Finally, due to the collective computation properties of some neural models, the area of artificial neural networks has contributed a third approach, although possibly not so relevant as the former ones, to the combinatorial optimization problem solving with the Hopfield nets (Hopfield, J.J. & Tank, D., 1985), the Boltzmann machine (Aarts, E.H.L. & Korst, J., 1989), and the self-organizing map (Kohonen, T., 1988).

Simulated Annealing Algorithm

The simulated annealing is a stochastic variant of the local search that incorporates a stochastic criterion of acceptance of worse quality solutions, in order to prevent the algorithm from being prematurely trapped in local optima. This acceptance criterion is based on the Metropolis algorithm for simulation of physical systems subject to a heat source (Metropolis, N., Rosenbluth, A., Rosenbluth, M., Teller, A. & Teller, E., 1953).

Algorithm (simulated annealing). Be a combinatorial optimization problem (X,S,f,R), with generator function of random k-neighbour feasible solutions \( g : S \times [0,1] \rightarrow S \). Supposing, without loss of generality, that \( f \) must be minimized, the simulated annealing algorithm can be described in the following way:

1. Set an initial random feasible solution as current solution, \( s_i = s_0 \).
2. Set initial temperature or control parameter \( T = T_0 \).
3. Obtain a new solution that differs from the current one in the value of \( k \) variables using the generator.
A Comparison of Cooling Schedules

function of random k-neighbour feasible solutions, 
$s_j = g(s_i, \text{random}[0,1])$.
4. If the new solution $s_j$ is better than the current 
one, $f(s_j) < f(s_i)$, then $s_i$ is set as current solution, 
$s_i = s_j$. Otherwise, if

$$
\frac{f(s_i) - f(s_j)}{\text{T}} > \text{random}[0,1]
$$

$s_j$ is equally accepted as current solution, $s_i = s_j$.
5. If the number of executed state transitions (steps 
3 and 4) for the current value of temperature is 
equal to L, then the temperature T is decreased.
6. If there are some k-neighbour feasible solutions 
ear to the current one that have not been processed 
yet, steps 3 to 5 must be repeated. The algorithm 
ends in case the set of k-neighbour solutions near 
to the current one has been processed completely 
with a probability close to 1 without obtaining any 
improvement in the quality of the solutions.

The most important feature of the simulated an-
nealing algorithm is that, besides accepting transitions 
that imply an improvement in the solution cost, it also 
allows to accept a decreasing number of transitions 
that mean a quality loss of the solution.

The simulated annealing algorithm converges 
asymptotically towards the set of global optimal solu-
tions of the problem. E. Aarts and J. Korst provide 
a complete proof in their book Simulated Annealing 
and Boltzmann Machines: A Stochastic Approach to 
Combinatorial Optimization and Neural Computing 
(1989). Essentially, the convergence condition towards 
global optimum sets that temperature $T$ of the system 
must be decreased logarithmically according to the 
equation:

$$
T_k = \frac{T_0}{1 + \log(1 + k)} \quad (1)
$$

where $k = 0,1,\ldots,n$ indicates the temperature cycle. 
However, this function of system cooling requires a 
prohibitive computing time, so it is necessary to con-
sider faster methods of temperature decrease.

Cooling Schedules

A practical simulated annealing implementation 
requires generating a finite sequence of decreasing 
values of temperature $T$, and a finite number $L$ of state 
transitions for each temperature value. To achieve this 
aim, a cooling schedule must be specified.

The following cooling schedule, frequently used in 
the literature, was proposed by Kirkpatrick, Gelatt and 
Vecchi (1983), and it consists of three parameters:

- **Initial temperature, $T_0$**. The initial value of temperature 
must be high enough so that any new solution generated in a state transition should be accepted with a certain probability close to 1.
- **Temperature decrease function**. Generally, an exponential decrease function is used, such as $T_k = T_0 \cdot \alpha^k$, where $\alpha$ is a constant smaller than the unit. Usual values of $\alpha$ fluctuate between 0.8 and 0.99.
- **Number of state transitions, $L$**, for each temperature value. Intuitively, the number of transitions for each temperature must be high enough so that, if no solution changes were accepted, the whole set of k-neighbour feasible solutions near to the current one could be gone round with a probability close to 1.

The initial temperature, $T_0$, and the number of state 
transitions, $L$, can be easily obtained. On the other hand, 
the temperature decrease function has been studied in 
numerous research works (Laarhoven, P.J.M. Van & 
Aarts, E.H.L., 1987), (Dowsland, K.A., 2001), (Luke, 
B.T., 2005), (Locatelli, M., 2000).

**MAIN FOCUS OF THE CHAPTER**

In this section nine different cooling schedules used in 
the comparison of the simulated annealing algorithm 
are described. They all consist of, at least, three pa-
rameters: initial temperature $T_0$, temperature decrease 
function, and number of state transitions $L$ for each 
temperature.

**Multiplicative Monotonic Cooling**

In the multiplicative monotonic cooling, the system 
temperature $T$ at cycle $k$ is computed multiplying the 
initial temperature $T_0$ by a factor that decreases with respect to cycle $k$. Four variants are considered:
