ABSTRACT

The objectives of this chapter are: (i) to introduce a concise overview of regularization; (ii) to define and to explain the role of a particular type of regularization called total variation norm (TV-norm) in computer vision tasks; (iii) to set up a brief discussion on the mathematical background of TV methods; and (iv) to establish a relationship between models and a few existing methods to solve problems cast as TV-norm. For the most part, image-processing algorithms blur the edges of the estimated images, however TV regularization preserves the edges with no prior information on the observed and the original images. The regularization scalar parameter λ controls the amount of regularization allowed and it is essential to obtain a high-quality regularized output. A wide-ranging review of several ways to put into practice TV regularization as well as its advantages and limitations are discussed.

1. INTRODUCTION

This chapter investigates robustness properties of machine learning (ML) methods based on convex risk minimization applied to computer vision. Kernel regression, support vector machines (SVMs), and least squares (LS) can be regarded as special cases of ML. The minimization of a regularized empirical risk based on convex functionals has an essential role in statistical learning theory (Vapnik, 1995), because (i) such classifiers are generally consistent under weak conditions; and (ii) robust statistics investigate the impact of data deviations on the results of estimation, testing or prediction methods.

In practice, one has to apply ML methods - which are nonparametric tools - to a data set with a finite sample size. Even so, the robustness is-
sue is important, because the assumption that all data points were independently generated by the same distribution can be contravened and outliers habitually occur in real data sets.

The real use of regularized learning methods depends significantly on the option to put together intelligent models fast and successfully, besides calling for efficient optimization methods. Many ML algorithms involve the ability to compare two objects by means of the similarity or distance between them. In many cases, existing distance or similarity functions such as the Euclidean distance are enough. However, some problems require more appropriate metrics. For instance, since the Euclidean distance uses of the $L_2$-norm, it is likely to perform scantily in the presence of outliers. The Mahalanobis distance is a straightforward and all-purpose method that subjects data to a linear transformation. Notwithstanding, Mahalanobis distances have two key problems: 1) the parameter vector to be learned increases quadratically as data grows, which poses a problem related to dimensionality; and 2) learning a linear transformation is not sufficient for data sets with nonlinear decision boundaries.

Models can also be selected by means of regularization methods, that is, they are penalizing depending on the number of parameters (Alpaydin, 2004; Fromont, 2007). Generally, Bayesian learning techniques make use of knowledge on the prior probability distributions in order to assign lower probabilities to models that are more complicated. Some popular model selection techniques are the Akaike information criterion (AIC), the Takeuchi information criterion (TIC), the Bayesian information criterion (BIC), the cross-validation technique (CV), and the minimum description length (MDL).

This chapter aims at showing how Total Variation (TV) regularization can be practically implemented in order to solve several computer vision applications although it is still a subject under research. Initially, TV has been introduced in (Rudin, Osher, & Fatemi, 1992) and, since then, it has found several applications in computer vision such as image restoration (Rudin & Osher, 1994), image denoising (Matteos, Molina & Katsaggelos, 2005; Molina, Vega & Katsaggelos, 2007), blind deconvolution (Chan & Wong, 1998), resolution enhancement (Guichard & Malgouyres, 1998), compression (Alter, Durand, & Froment, 2005), motion estimation (Drulea & Nedevschi, 2011), texture segmentation/discrimination (Roudenko, 2004). These applications involve the use of TV regularization that allows selecting the best solution from a set of several possible ones.

2. BACKGROUND

2.1. Regularization

In machine learning (ML) and inverse problems, regularization brings in extra information to solve an ill-posed problem and/or to circumvent over-fitting. Representative information is taken into consideration via insertion of a penalty function based on constraints for solution smoothness or bounds on the vector space norm. Representative cases of regularization in statistical ML involve methods like ridge regression, lasso, and $L_2$-norm for example.

If a problem has (a) a unique solution, and (b) the solution is robust to small data perturbations, then it is called well-posed. When at least one of them is violated, it is named ill-posed and it requires special care.

Non-uniqueness is a consequence of not having enough data on the original model and it is not detrimental at all times. Depending on the desired characteristics of a good solution or some measures of goodness, then an estimate can be picked up from a set of multiple solutions. Nevertheless, if one does not know how to evaluate an estimate, then a very good way to handle non-uniqueness is to enforce some prior information about domain in order to constrain the solution set.

Instability results from an effort to undo cause-effect relations. Solving a forward problem is the
